ABSTRACT

We present results of a new feedback scheme implemented in the Munich galaxy formation model. The new scheme includes a dynamical treatment of galactic winds powered by supernovae explosions and stellar winds and is an excellent alternative to empirically-motivated recipes for feedback in galaxy formation. Model results are in good agreement with the observed luminosity function and stellar mass function for galaxies in the local Universe. In particular, the new scheme predicts a number density of dwarfs that is lower than in previous models. The model is also able to reproduce the observed mass–stellar metallicity and luminosity–gas metallicity relations. This demonstrates that our scheme provides a significant improvement in the treatment of the feedback in dwarf galaxies. A new feature of the model allows an estimate of the amount of mass and metals that haloes can permanently deposit into the IGM. It is this loss of material that leads to a suppression of star formation in small haloes and therefore to a decrease in the number density of dwarf galaxies. Despite its successes, our model does not reproduce the observed bimodality in galaxy colours. Finally, we investigate the efficiency of mass and metal injections in winds and in the intergalactic medium. We find that galaxies that reside in haloes with $M_{\text{vir}} < 10^{12.5} M_{\odot}$ may deposit most of their metal mass into the intergalactic medium, while groups and clusters at $z = 0$ have lost at most a few percent of their metals before the bulk of the halo mass was accreted.

Key words: methods: numerical – galaxies: formation – galaxies: evolution – galaxies: abundances

1 INTRODUCTION

Dwarf galaxies are the most abundant galactic objects in the universe and play a key role in galaxy formation. Because of their shallow gravitational potentials, feedback from star formation is most efficient in these galaxies and is believed to successfully eject a large amount of their gas and metals (e.g. Larson 1974; Dekel & Silk 1986; Mac Low & Ferrara 1999; Springel & Hernquist 2003; Veilleux, Cecil & Bland-Hawthorn 2005 and references therein). As a consequence, dwarf galaxies may have a fundamental role in polluting the diffuse intergalactic medium (IGM, hereafter) with the products of stellar nucleosynthesis (e.g. Aguirre et al. 2001; Theuns, Mo & Schaye 2001; Springel & Hernquist 2003; Bertone, Stoehr & White 2005; Oppenheimer & Davé 2006).

Observations of galaxies and their gas content in the

local universe indicate that feedback in the form of galactic winds plays an important role in regulating star formation (Garnett 2002; Kauffmann et al. 2003; Tremonti et al. 2004; Salzer et al. 2005). As mentioned above, the impact of feedback is believed to be strongest in dwarfs. It is however important to note that feedback can be equally effective in temporarily reheating the interstellar medium and quenching star formation in more massive galaxies (Heckman et al. 2000; Cecil et al. 2001; Rupke, Veilleux & Sanders 2002; Shapley et al. 2003; Rupke & Veilleux 2005). A variety of observational data suggests that, for each unit of gas mass that is converted into stars, an equal or larger amount of interstellar gas can be reheated and ejected from the disk of a galaxy (Martin 1999; Pettini et al. 2002; Rupke & Veilleux 2005; Martin 2006). Since the ejected mass may be lost to the galaxy and deposited into the IGM, this has a dramatic effect on the total amount of stars that can be formed in a galaxy during its lifetime.

* E-mail: s.bertone@sussex.ac.uk

By regulating star formation, feedback also alters

the properties of the entire galaxy population. The shape of the luminosity function (i.e. the space density of galaxies as a function of their luminosity) is believed to reflect the effects of different feedback mechanisms. Different studies have demonstrated that feedback by galactic winds is responsible for shaping the faint end of the luminosity function (White & Rees 1978; Dekel & Silk 1986; Kauffmann, White & Guiderdoni 1993; Somerville & Primack 1999; Benson et al. 2003). More recent work has focused on feedback from accreting black holes in active galactic nuclei (AGN feedback, hereafter) as an important physical mechanism to suppress the cooling flows in relatively massive haloes (Di Matteo et al. 2005; Croton et al. 2006; Bower et al. 2006).

While some of the gas (and metals) ejected by winds may fall back onto the galaxy at a later time via galactic fountains or gravitational accretion, a fraction of the ejected material may be deposited permanently into the IGM. Metals have been detected in the lowest density regions of the universe probed by the Ly α forest in the spectra of high-redshift quasars, and the IGM metallicity has been estimated to be in the range $10^{-3} - 10^{-2} Z_{\odot}$ (Songaila & Cowie 1996; Rauch 1998; Schaye et al. 2000; Schaye et al. 2003; Aguirre et al. 2004; Simcoe, Sargent & Rauch 2004). Although most of the intergalactic metals appear to be associated with galaxies (Adelberger et al. 2005; Stocke et al. 2006), a significant fraction does not show such a correlation (Pieri et al. 2006). Galaxies remain the best candidates to explain the enrichment of regions at larger overdensities, such as filaments, groups and clusters (Aguirre et al. 2001; Theuns et al. 2002; De Lucia et al. 2004; Bertone, Stoehr & White 2005; Daigne et al. 2006; Oppenheimer & Davé 2006). As for the enrichment of the lowest density regions, it is still not clear which is the contribution from the first populations of stars (Murakami et al. 2005; Matteucci & Calura 2005).

In this work, we implement a dynamical treatment of galactic winds in a galaxy formation model in order to test if this leads to any improvement on previous feedback schemes. In particular, we use an updated version of the wind model by Bertone, Stoehr & White (2005) and the Munich galaxy formation model used in De Lucia & Blaizot (2007) (DLB07 hereafter). Our wind model entirely replaces the supernovae feedback scheme used in the semi-analytic model but it does not affect the AGN feedback, which does not depend on star formation (Croton et al. 2006). We apply our model to the Millennium Simulation (Springel et al. 2005) and we compare our model results to those from the latest Millennium galaxy catalogue from DLB07¹.

This paper is organised as follows. In Section 2 we describe the new features of our feedback scheme and its implementation in the Millennium simulation. Section 3 shows results for the galaxy luminosity functions, the stellar mass function, galaxy colours, and morphological fractions at $z = 0$. In Section 4 we discuss the impact of winds on the chemical evolution of galaxies. Finally, in Section 5 we investigate the role of winds in recycling gas and metals, and

in enriching the IGM through the cosmic time. We draw our conclusions in Section 6.

2 GALAXY FORMATION

In this work we use the Millennium simulation² to trace the evolution of dark matter haloes in a cubic box of $500 h^{-1} \text{Mpc}$ on a side (Springel et al. 2005). The underlying cosmological model is a Λ CDM cosmology consistent with a combined analysis of the 2dFGRS and first year WMAP data (Spergel et al. 2003). The cosmological parameters are $\Omega_m = 0.25$, $\Omega_b = 0.045$, $h = 0.73$, $\Omega_{\Lambda} = 0.75$, $n = 1$, and $\sigma_8 = 0.9$. The Hubble constant is parameterised as $H_0 = 100 h^{-1} \text{km s}^{-1} \text{Mpc}^{-1}$. The simulation follows $N = 2160^3$ dark matter particles of mass $8.6 \times 10^8 M_{\odot}$.

As basis for our model, we use the galaxy formation model of DLB07. We refer the reader to the original paper for more details about the different physical processes explicitly modelled and their implementation. We note that the model used in DLB07 retains many prescriptions of the previous version of the Munich galaxy formation models described in Croton et al. (2006), but differs in a number of details. DLB07 use a different construction of the dark matter merger trees, modified as to effectively track the most massive progenitor history. DLB07 adopt a Chabrier initial mass function (Chabrier 2003) and an improved treatment of dust attenuation which takes into account the attenuation of young stars within their birth clouds. In this work, we use the same set of parameters adopted in DLB07. The feedback parameters ϵ_{disk} , ϵ_{halo} and the reincorporation parameter γ_{ej} (see Table 1 in Croton et al. (2006) are not used in our model. Our wind scheme also contains free parameters, which we discuss in the following and summarise in Table 1.

2.1 A dynamical feedback model

The feedback model used here is based on the work by Bertone, Stoehr & White (2005). Galactic winds are treated as spherical blastwaves, powered by supernova explosions and stellar winds, which expand in a cosmological context. The physics of galactic winds is described by the equation of motion that governs their dynamical evolution.

The main difference between this analysis and that of Bertone, Stoehr & White (2005) resides in the fully self-consistent treatment of feedback. While in Bertone, Stoehr & White (2005) winds are added “on top” of the semi-analytic prescriptions for galaxy formation, here we integrate the dynamic treatment of winds together with the existing prescriptions for star formation, chemical evolution and gas cooling. This results in a scheme in which the ejection and recycling of gas and metals is dictated by the dynamic evolution of the winds, rather than by phenomenological recipes (Kauffmann, White & Guiderdoni 1993; Somerville & Primack 1999; Kauffmann et al. 1999; Springel et al. 2001; De Lucia et al. 2004; Croton et al. 2006). An alternative, dynamically-motivated approach to

² <http://www.mpa-garching.mpg.de/galform/virgo/millennium>

feedback in semi-analytic models has recently been presented by Monaco (2004).

We describe the dynamical evolution of a wind as a two-phase process: a pressure-driven, adiabatic expansion, followed by a momentum-driven snowplough. During the first phase, a spherical bubble of hot gas blows out the disk of a galaxy and a wind is formed. The expansion of the bubble is driven by the pressure of the outflowing gas and the equation of motion is expressed by the conservation of the bubble energy E_b :

$$\frac{dE_b}{dt} = \frac{1}{2} \dot{M}_w v_w^2(R) - \frac{d\Delta W}{dt} + 4\pi R^2 \cdot \left\{ \left[\frac{1}{2} \rho_o v_o^2 + u_o - \rho_o \frac{GM_h}{R} \right] (v_s - v_o) - v_o P_o \right\} \quad (1)$$

R and v_s are the radius and the velocity of the shock, \dot{M}_w and $v_w(R)$ the mass outflow rate and the outflow velocity of the wind at the shock radius (see Subsec. 2.2). ρ_o , P_o , u_o and v_o are the density, the pressure, the internal energy and the outward velocity of the surrounding medium and M_h the total mass internal to the shock radius. The term $d\Delta W/dt$ indicates the rate at which gravitational energy is transferred from the swept-up gas to the other components (Ostriker & McKee 1988). The expansion of a wind is determined by the balance between the forces acting on the wind: the injection of energy and momentum from SN accelerates the expansion, while the combined effect of gravity, thermal pressure, and ram pressure slows it down and might eventually make the wind collapse.

When radiative losses become dominant and most of the energy transferred to the swept-up gas is radiated away, the adiabatic phase is terminated and a thin shell of cooled gas forms near the outer edge of the bubble. This typically happens when the cooling time of the bubble becomes shorter than the age of the wind. When the snowplough phase sets in, the expansion of the shell is described by the conservation of the wind momentum:

$$\frac{d}{dt}(mv_s) = \dot{M}_w (v_w(R) - v_s) - \frac{GM_h}{R^2} m - 4\pi R^2 [P_o + \rho_o v_o (v_s - v_o)], \quad (2)$$

where m is the mass of the shell.

The only formal difference between these equations and those used in Bertone, Stoehr & White (2005) consists in the removal of the free parameter ε . This means that a wind expanding into a halo sweeps up all the hot gas it encounters on its path, instead of just a fraction of it. It is therefore equivalent to assuming $\varepsilon = 1$. In our model winds are powered by all galaxies in a halo and effectively blow “from haloes”, receiving energy, momentum and mass from all the galaxies in the halo (see sec. 2.3). When haloes merge and a former central galaxy becomes a satellite, its wind is transferred to the central galaxy of the merged halo. If the central galaxy is already blowing a wind, the two are combined under the assumption that mass, energy and momentum are conserved. The mass and the metals ejected into the IGM by the merged galaxies are added to the ejected component of the new central galaxy.

If the momentum of the outflowing material is not able to balance the momentum losses by gravity and pressure forces, the wind can collapse and create a galactic fountain. The dynamics of the collapsing wind can be traced by Eq. (2)

until the shell falls back onto the central galaxy. We assume that all the mass in the collapsed wind is instantaneously reincorporated into the hot component of the halo. In previous schemes (De Lucia et al. 2004; Croton et al. 2006) the ejected material is reincorporated into the hot component, thereafter being again available for cooling, on a time-scale that is proportional to the dynamical time-scale of the halo. De Lucia et al. (2004) argue that various observational results can be reproduced only by models in which the ejected material is re-incorporated on a time-scale comparable to the age of the Universe.

If a large amount of energy and momentum is injected in a bubble, a wind can overcome gravity and pressure forces and expand to a large radius. When the wind reaches the Hubble flow, it escapes from the halo and its mass and metals are lost for ever from the galaxy. We define the transition between the halo environment and the Hubble flow as the point where the velocity of the surrounding medium, defined as $v_o = RH(z) - v_{\text{esc}}(R)/2$, is dominated by the Hubble flow term and becomes positive. Here, $H(z)$ is the Hubble constant at redshift z and $v_{\text{esc}}(R)$ is the escape velocity of the halo at radius R , calculated assuming a NFW profile (Navarro, Frenk & White 1996). A consequence of this assumption is that the maximum radius to which winds can travel is proportional to the virial mass of the halo. Winds outflowing from small haloes escape at smaller radii than winds expanding out of larger haloes. In the following, we will call “mass in IGM” the wind mass that reaches the Hubble flow. This material cannot be re-incorporated and therefore does not participate again in the evolution of the galaxy.

2.2 Mass and metals in winds

The evolution and exchange of metals between the different galactic components follows the same scheme proposed in De Lucia et al. (2004), modified to integrate self-consistently the removal of gas and metals from the cold gas. When stars form, metals are produced and instantaneously returned to the interstellar medium. Subsequently, they can be deposited into the hot gas and ejected component by feedback processes.

During the adiabatic phase, the outflowing mass creates the over-pressurized bubble of hot gas. The mass of the bubble M_b is determined by the conservation of mass law:

$$\frac{dM_b}{dt} = \dot{M}_w + 4\pi R^2 \rho_o (v_s - v_o), \quad (3)$$

where the first term on the right hand side represents the mass of cold gas reheated by SN explosions and stellar winds and the second term defines the amount of hot gas swept up by the wind and accreted during the expansion in the halo. In a snowplough, most of the mass accumulates in a thin shell of mass m :

$$\frac{dm}{dt} = \dot{M}_w \left(1 - \frac{v_s}{v_w(R)} \right) + 4\pi R^2 \rho_o (v_s - v_o). \quad (4)$$

A fraction $\dot{M}_w v_s / v_w(R)$ of the outflowing ISM does not reach the shell and remains in the cavity behind the shock. Assuming that the amount of metals exchanged is proportional to the corresponding amount of mass (i.e. neglecting any metal-loading effect), the corresponding equations for

Model parameter	Fiducial value
η	2
V_w	800 km s ⁻¹
α_w	2

Table 1. Summary of model parameters.

metals are:

$$\frac{dM_{bz}}{dt} = \dot{M}_w Z_{\text{cold}} + 4\pi R^2 \rho_o (v_s - v_o) Z_{\text{hot}}, \quad (5)$$

where Z_{cold} is the metallicity of the cold gas and Z_{hot} the metallicity of the hot gas, and:

$$\frac{dm_z}{dt} = \dot{M}_w \left(1 - \frac{v_s}{v_w(R)} \right) Z_{\text{cold}} + 4\pi R^2 \rho_o (v_s - v_o) Z_{\text{hot}}, \quad (6)$$

A fraction $Z_{\text{cold}} \dot{M}_w v_s / v_w(R)$ of the outflowing metals remains in the cavity behind the shell.

Eqs. 3–6 imply that the amount of mass and metals ejected from the cold gas are $\dot{M}_w dt$ and $\dot{M}_w Z_{\text{cold}} dt$ respectively. The amount of mass and metals removed from the halo hot gas and swept up on to a wind are $4\pi R^2 \rho_o (v_s - v_o) dt$ and $4\pi R^2 \rho_o (v_s - v_o) Z_{\text{hot}} dt$ respectively. The removal of hot gas from the halo is in principle similar to the implementation of the “ejected mass” in the Croton et al. (2006) model, but here it is justified on the basis of the dynamical evolution of the winds and their sweeping up the gas on the path of the expansion.

2.3 Wind initial conditions and model parameters

Our description of the physics of winds contains three free parameters in the wind initial conditions: the wind initial velocity V_w , the wind mass loss rate η and the power law index α_w . Table 1 summarises the values of the parameters used in our fiducial model. This set of initial conditions differs from that used in Bertone, Stoehr & White (2005), who used the parametrisation for v_w and \dot{M}_w proposed by Shu, Mo & Mao (2005).

Observations of galaxies in the local and high redshift universe suggest that the mass loss rate of winds is roughly proportional to the star formation rate (Martin 1999; Pettini et al. 2002; Rupke & Veilleux 2005; Martin 2006). In our model, we parametrise the mass loss rate \dot{M}_w as a function of the star formation rate \dot{M}_\star and of the virial velocity of the halo v_{vir} :

$$\dot{M}_w = \eta \dot{M}_\star \left(\frac{220 \text{ km s}^{-1}}{v_{\text{vir}}} \right)^{\alpha_w}. \quad (7)$$

In the above equation, \dot{M}_w represents the sum of the star formation rates of all the galaxies in a halo. According to this choice, all galaxies in a halo can contribute to power the corresponding wind and to eject mass and metals. The dependence of the wind mass loss rate on the halo virial velocity $v_{\text{vir}}^{-\alpha_w}$ implies that the ratio $\dot{M}_w / \dot{M}_\star$ is highest in the smallest haloes. We note that this definition of the mass loss rate is equivalent to that of the reheated mass in De Lucia et al. (2004). In our fiducial model we assume $\eta = 2$ and $\alpha_w = 2$.

At the galactic radius R_{gal} , where energy and momentum are injected into the wind, the initial wind velocity

$v_{w0} = v_w(R_{\text{gal}})$ is calculated assuming that the energy injection rate in winds $\dot{E}_w = \dot{M}_w v_{w0}$ is independent of halo properties. Given the dependence of the mass loss rate on v_{vir} in Eq. 7, the wind initial velocity can be expressed as

$$v_{w0} = V_w \left(\frac{220 \text{ km s}^{-1}}{v_{\text{vir}}} \right)^{-\alpha_w/2}. \quad (8)$$

We choose as fiducial value $V_w = 800 \text{ km s}^{-1}$. The wind velocity at a radius r is calculated as $v_w^2(r) = v_{w0}^2 - 2[\phi(r) - \phi(R_{\text{gal}})]$, where ϕ is the gravitational potential of the halo, calculated assuming an NFW profile.

Observations of galaxies both in the local and the high redshift universe estimate wind velocities in the range 100–1500 km s⁻¹ (Strickland & Stevens 2000; Frye, Broadhurst & Benitez 2002; Shapley et al. 2003; Rupke & Veilleux 2005; also see Veilleux, Cecil & Bland–Hawthorn 2005 for a complete review of the phenomenology of galactic winds). Since winds are multiphase phenomena, the detection of the outflowing gas in different wavebands gives information about wind gas components at different temperatures. These may yield very diverse values for the wind velocity. The X-ray emitting gas is believed to represent the most energetic phase of the wind, containing most of the metal-rich supernova ejecta. Simulations by Strickland & Stevens (2000) demonstrate that this gas is outflowing with the highest velocities, but it is not representative of the bulk of the mass in winds. The latter – that is what our wind model is meant to describe – can be detected in less energetic wavebands and has much lower velocities (Rupke & Veilleux 2005; Heckman et al. 2000). We note that in our model, we assume that supernova ejecta efficiently mix with the ISM before leaving the disk of the galaxy.

Although the large wind velocities given by Eq. 8 seeming to indicate that winds can escape from large haloes, this never occurs in practise. As we will show in the following, in haloes with $M_{\text{vir}} \gtrsim 10^{12.5} M_\odot$ the injected energy is never large enough to overcome the gravitational potential and the pressure forces of the intra-cluster gas. In these haloes, the wind usually collapses within a few time-steps and its mass and metals are reincorporated into the hot gas.

3 THE ABUNDANCE OF GALAXIES

In this Section we present results for the galaxy luminosity functions (LFs hereafter, Subsec. 3.1), the stellar mass function (Subsec. 3.2), and the morphology distribution of galaxies at $z = 0$ (Subsec. 3.3). We discuss galaxy colours in Subsec. 3.4. Throughout, we highlight the role of winds in suppressing star formation in faint galaxies, which is, perhaps, the most important achievement of our model.

3.1 Galaxy luminosity functions

Figs. 1 and 2 show the galaxy K-band and b_J -band LFs from our model (solid line) and the corresponding observational data from the 2 degree Field Galaxy Redshift Survey (Coles et al. 2001, 2dFGRS hereafter) and the 6 degree Field Galaxy Survey (Jones et al. 2006, 6dFGS hereafter). In both figures, the dashed line shows the corresponding luminosity function from the model of DLB07.

Figure 1. K-band galaxy luminosity function at $z = 0$. Results from this work (solid line) are compared to observational data from the 2dFGRS (Coles et al. 2001) and 6dFGS (Jones et al. 2006) surveys (filled squares and circles respectively). The dashed line shows the corresponding luminosity function from the model of DLB07.

Figure 2. As in Fig. 1 but for the b_J -band galaxy luminosity function at $z = 0$.

Our predictions differ from those of DLB07 both at the faint and at the bright end of the LFs. Our model predicts a shallower faint end slope than DLB07, bringing the abundance of the faint model galaxies closer to the observed values. Although the agreement with observational data is still not perfect, it improves the results of DLB07 by a factor of two for galaxies fainter than $M_K > -22$. The ability to accurately reproduce the slope of the faint end of the galaxy LFs is peculiar to our model and is a consequence of our new feedback scheme. In addition, the slope of the galaxy LFs

Figure 3. Stellar mass function at $z = 0$. Numerical results for our model and for DLB07 are compared to the observations of Bell et al. (2003) and Panter et al. (2004).

does not appear to be sensitive to the parameters regulating our feedback scheme. DLB07 predict a bump in the b_J -band LF around $M_{b_J} \sim -16$ and a steeper slope for the faint end of the K-band LF, which are not seen in observations. We have found that our model can reproduce these two features only when feedback is particularly inefficient in dwarfs (i.e. $\alpha_w = 0$, or V_w and η have very low values). In this case, the energy injected in winds is not enough to overcome the gravitational potential of even the smallest haloes, leading to a severe overestimation of the number of faint galaxies.

Figs. 1 and 2 also show that our model overpredicts the abundance of bright galaxies both in the b_J - and in the K-band. This overprediction is a consequence of the short reincorporation time-scales obtained for relatively massive haloes. In our model, winds in haloes with $M_{\text{vir}} \gtrsim 10^{12.5} M_\odot$ are unable to escape the gravitational potential and typically collapse after a few million years. The mass of the collapsing wind is instantaneously reincorporated into the hot gas and is again available for cooling, contributing to increase the luminosity of the central galaxy. This problem could partly be solved by assuming a higher efficiency for the AGN feedback (20–30 per cent higher than in Croton et al. 2006) or by increasing the reincorporation timescale of collapsed winds in large haloes (as in De Lucia et al. 2004). However, since the aim of this work is to test the performance of a dynamical wind model in shaping the galaxy properties, assuming a non-instantaneous reincorporation time-scale defeats the main purpose of the model.

3.2 Stellar mass function

In this Subsection we focus on the stellar mass function of galaxies at $z = 0$.

We show the stellar mass function of galaxies in Fig. 3. Our results are compared to the observations of Bell et al. (2003) and Panter et al. (2004) and to the model of DLB07. We use the mass function results of Bell et al. (2003) ob-

tained from the SDSS g -band. Our model shows a better agreement with the observed stellar mass functions than DLB07, and in particular it better reproduces the number density of faint galaxies and of the brightest galaxies. However, both our model and the model of DLB07 underpredict the spatial density of M^* galaxies at the knee of the distribution, for $10^{10.5}M_\odot < M_* < 10^{11.5}M_\odot$.

The stellar mass function should closely reflect the K-band LF. Although at first sight the lack of galaxies around M^* does not seem to appear in the K-band LF (Fig. 1), if we shifted the LF to lower luminosities by about 0.5 mag, we would recover exactly the same effect. This may be an indication that the galaxy luminosities are overestimated, or that the galaxy formation model is unable to produce as many M^* galaxies as there are in the real universe.

We believe that the underestimation of the abundance of M^* galaxies is due to a combination of effects. In this range of stellar masses the effects of galaxy and AGN feedback overlap and as a result star formation may be suppressed more strongly than in other mass ranges. We find two possible ways to solve this problem. An overall increase in the efficiency of star formation or, alternatively, a decrease in the efficiency of feedback in galaxies as bright or brighter than M^* helps to produce more galaxies at the knee, and in particular more early types. However, in the first case, much higher feedback is required to suppress the formation of dwarf galaxies and predict the correct slope of the faint end of the stellar mass function. On the other hand, reducing the efficiency of feedback in M^* galaxies would imply that the efficiency to deposit supernova energy in winds depends critically on some unknown galaxy properties. In either case, there might be a connection between physical processes taking place at scales not resolved by current simulations and the efficiency of star formation and feedback that we have not been able to include in our modelling of galaxy formation.

3.3 Galaxy morphologies

In this section we analyse the morphological mix of our model galaxies at $z = 0$. Fig. 4 shows the fraction of galaxies with different morphological types as a function of stellar mass. Data points in Fig. 4 show observational determinations from Conselice (2006), who analysed a sample of about 22000 galaxies with a visual morphological classification from the RC3 catalogue (de Vaucouleurs et al. 1991). As a proxy for the morphology of our model galaxies, we use the ratio between the bulge mass and the total stellar mass ($r = M_{\text{bulge}}/M_*$). In particular, we classify as ellipticals galaxies with more than 70 per cent of their stars in the bulge ($r > 0.7$), as irregulars all galaxies without a bulge ($r = 0$), and as spirals all galaxies with $0 < r \leq 0.7$. The threshold value $r = 0.7$ is fixed arbitrarily, but results do not depend significantly on it. In particular, independently of the value of r , we find that ellipticals represent the dominant type at the highest stellar masses, while the smallest galaxies are predominantly irregulars. Most of the galaxies with $10^{9.5}M_\odot < M_* < 10^{11}M_\odot$ have a spiral morphology. A lower value of r would slightly decrease the fraction of spirals at intermediate stellar masses, while a higher value would slightly increase it.

Fig. 4 show that our model reproduces quite nicely the

Figure 4. Fraction of galaxy morphological types as a function of stellar mass. We define as ellipticals all galaxies with a dominant bulge component ($M_{\text{bulge}}/M_* > 0.7$), as spirals all galaxies with $0 < M_{\text{bulge}}/M_* < 0.7$, and as irregulars all galaxies with no bulge. Model results are compared to the observational determination of Conselice (2006). Thick coloured lines show the results of this work, while thin black lines are for the model of DLB07.

observational results. The main difference with the model predictions of DLB07 is found for the highest and lowest stellar mass galaxies. In the highest stellar mass bin our model does predict a few spiral galaxies, in agreement with observations. The model of DLB07 does not predict any spiral in this mass range, even assuming a value of $r = 0.6$. This difference is due to the recycling of gas in our feedback model, which is particularly efficient for galaxies in groups with $M_{\text{vir}} \gtrsim 10^{13}M_\odot$. This results in galaxies with larger stellar masses to have larger disks in our model. We will discuss this feature of our model in more detail in Subsec. 5.1. In the intermediate mass range, our model predicts a lower fraction of spirals than DLB07, in better agreement with observational results. In the lowest mass bins, our model predicts a non-zero fraction of spiral and elliptical galaxies and a fraction of irregular galaxies lower than 1. We note, however, that the morphological classification might not be ‘robust’ for model galaxies in this mass range as they reside in haloes whose history can be followed back in time only for a few time-steps.

In our semi-analytic model the mass of the bulge is determined by two processes: mergers and dynamical instabilities of the disk. As explained in detail in Croton et al. (2006) and De Lucia et al. (2006), the disk instability is treated as in Mo, Mao & White (1998) and depends on the density of stars in the galaxy disk. The outcome of a galaxy merger depends on the baryonic mass ratio of the merging galaxies. Our feedback scheme modifies the mass of gas and stars in galaxies (e.g. see Fig. 3) and so directly affects the morphological mix of model galaxies.

Figure 5. The $B - V$ colours of model galaxies as a function of their stellar mass. The upper panel shows results from the model discussed in this paper while the lower panel shows result from DLB07. Galaxies are defined as “late types” and “early types” according to their bulge-to-total luminosity ratio in B-band. The vertical dashed line marks the limit where the morphological classification of model galaxies can be considered robust.

3.4 Galaxy colours

In this Subsection we briefly discuss the colours of galaxies and the colour-magnitude relationship. Fig. 5 shows the $B - V$ colour of model galaxies as a function of stellar mass. The upper panel shows results from the model discussed in this paper while the lower panel shows results from DLB07. Note that this figure corresponds to Fig. 9 of Croton et al. (2006). As in that work, the morphology of model galaxies is here defined on the basis of their bulge-to-total luminosity ratio in B-band. The vertical line indicate the limit above which the morphological classification can be considered robust.

Fig. 5 indicates that there are several differences between our model and the model of DLB07. While DLB07

predicts a sharp colour bimodality, our model shows a much smoother distribution of galaxy colours, with few blue galaxies and most of the galaxies residing on a red sequence which appears steeper and characterised by a larger scatter than the model results from DLB07. The suppression of the colour-bimodality is a consequence of the wind model. We have verified that most combinations of parameters yield to a distribution similar to that shown in the upper panel of Fig. 5. A somewhat sharper bimodality can be obtained only in models with high values of the mass loss rate parameter η . The results shown in Fig. 5 explain that our model predicts a lower (with respect to DLB07) abundance of red ($B - V > 0.8$), faint galaxies because the new feedback scheme leads to a steeper colour-magnitude relation.

4 CONSEQUENCES FOR THE CHEMICAL EVOLUTION OF GALAXIES

In this Section we analyse how the stellar and gas metallicities of our model galaxies relate to their mass or luminosity, and compare our results to different observational measurements. The ability of a galaxy formation model in reproducing the observed correlations provide important constraints on how well the circulation of baryons in the different components is modelled.

As explained in Kauffmann (1996), the use of a surface density threshold for the star formation, naturally reproduces the observed trend of the gas fraction as a function of galaxy luminosity. Our results are very similar to those shown in De Lucia et al. (2004) and Croton et al. (2006) so we do not repeat them here.

4.1 The metallicities of stars

Fig. 6 shows our results for the metallicity of the stellar component of galaxies and compares them to the observational measurements by Gallazzi et al. (2005) and to the model results by DLB07. All model galaxies have been used here. Gallazzi et al. (2005) analyse about 44000 galaxies from the SDSS DR2 and find that the stellar metallicity increases with stellar mass up to $M_* \sim 10^{10.5} M_\odot$. For larger masses, the metallicity distribution flattens and saturates to a super-solar value. The stellar metallicity also flattens for $M_* \lesssim 10^{9.5} M_\odot$. Our model predicts a trend roughly similar to the observational data, although the distribution of the simulated metallicities shows a smaller scatter. The model discussed in DLB07 exhibits an even smaller scatter and a shallower relation that appears to be in less good agreement with observational results. None of the two models exhibits the observed flattening for $M_* < 10^{9.5} M_\odot$.

We argue that the change in slope of the metallicity-mass relation in our model is a consequence of the feedback scheme. As we will show in the following, galaxies in haloes with $M_{\text{vir}} < 10^{12.5} M_\odot$ eject a larger fraction of their gas mass in winds and in the IGM than galaxies in larger haloes (see Sec. 5). This halo mass roughly corresponds to stellar masses of about $M_* \sim 10^{10.5} M_\odot$. The high efficiency of the ejection of mass in small haloes strongly suppresses the formation of stars in these galaxies and therefore affects the amount of metals that can be produced and locked into their stellar component, ultimately shaping the distribution

Figure 6. Stellar metallicity as a function of stellar mass. The large dots and the shaded region represent the median and the 16th and 84th percentiles of the distribution measured for a sample of SDSS galaxies by Gallazzi et al. (2005). The solid and dashed lines show the same quantities for the model presented here and for the model of DLB07 respectively.

of the stellar metallicities. We have experimented with different sets of parameters and verified that the change in slope always appears where the efficiency of winds in ejecting gas from galaxies drops.

4.2 Luminosity–gas metallicity relationships

Fig. 7 shows the optical luminosity–gas metallicity relationships in B-band and K-band and compares the model results with fits to observational data from Salzer et al. (2005) and Tremonti et al. (2004). Tremonti et al. (2004) estimate the oxygen abundance in SDSS galaxies by fitting simultaneously the most prominent emission lines with a model for integrated galaxy spectra (Charlot & Longhetti 2001). Salzer et al. (2005) use a sample of several hundred galaxies from the Kitt Peak National Observatory International Spectroscopic Survey (KISS, Salzer et al. 2000). They use two different metallicity calibrations: from Edmunds & Pagel (1984, hereafter EP) and from Kennicutt et al. (2003, hereafter KBG). As can be seen from Fig. 7, different metallicity calibrators give slightly different estimates of the oxygen abundance in nebular emission lines. Results from our model appear to be in very good agreement with the EP fit by Salzer et al. (2005) for $M_B < -20$ and $M_K < -24$. At the brightest magnitudes, the luminosity–gas metallicity relation changes slope and model results appear to be closer to the fit corresponding to the KBG calibrator. The estimate of Tremonti et al. (2004) intercepts the upper end of the distribution of the numerical results in B-band.

To estimate the oxygen abundance of model galaxies, we assume a solar oxygen abundance of $12 + \log_{10} [O/H]_{\odot} = 8.76$. The latest determinations of the solar oxygen abundance range from $12 + \log_{10} [O/H]_{\odot} = 8.66$ as estimated by Asplund, Grevesse & Sauval (2006) using photospheric

Figure 7. Gas metallicity as a function of the magnitude in B-band (upper panel) and in the K-band (lower panel). The black solid line shows the median of the distribution for model galaxies. The yellow marks the region including the 16th and 84th percentiles of the distribution. Observational determinations from Salzer et al. (2005) (using two different calibrations) and Tremonti et al. (2004) are shown as dashed and dot-dashed lines respectively.

abundances, to $12 + \log_{10} [O/H]_{\odot} = 8.86$ as estimated by Delahaye & Pinsonneault (2006) on the basis of helioseismology results. The higher value of $12 + \log_{10} [O/H]_{\odot}$ would bring our results in better agreement with the fit by Tremonti et al. (2004), while the lower value would give a better agreement with the KBG fit. Independently of the normalization adopted, however, our predictions nicely match the observed slope of the luminosity–metallicity relationship in both B-band and K-band. Different combinations of model parameters shift the relation upwards or downwards by a few percent, but do not affect the slope or the scatter of the distribution. The dotted lines in Fig. 7

show the corresponding relationships from the model of DLB07. When compared to our model results, this model predicts a shallower relation in the B-band and a non-linear relation in the K-band. Faint galaxies with $M_B > -18$ and $M_K > -20$ show the largest deviations from the observed metallicities. The model of DLB07 also features a smaller scatter than our model.

Overall, the good agreement between the observed stellar and nebular metallicities and the predictions of our model is an indication that the dynamical feedback scheme for galactic winds is well integrated with the chemical evolution of galaxies. On the other hand, Figs. 6 and 7 indicate that the model of DLB07 may significantly overestimate the metallicities of faint galaxies, indicating perhaps an incorrect treatment of feedback in these galaxies.

5 THE ADVENTURES OF METALS TRAVELLING WITH WINDS

In this Section we follow the path of the metals that have been injected in winds and take an active part in the cycle of star formation and feedback. In Subsection 5.1 we focus on the recycling of metals during feedback and we attempt to map the inter-dependent evolution of galaxies and winds. In Subsection 5.2 we trace the history of the deposition of metals into the IGM through cosmic time and investigate which galaxies are the main sources of the metal enrichment of the IGM.

5.1 Recycling metals in galactic winds

Feedback processes, and supernova feedback in particular, determine the recycling of gas between episodes of star formation. In this Subsection we investigate how our model treats metals during this recycling process and we highlight the main differences between this wind scheme and the feedback scheme of DLB07.

As described earlier, only in some haloes galaxies release enough energy in supernovae explosions to blow winds to distances comparable or larger than the virial radius of the halo. Of these, only a fraction will permanently deposit their mass and metals into the IGM. In our model, most winds start blowing with such a little initial energy - compared to the energy required to overcome the gravitational and pressure forces of the halo - that they collapse after a few time-steps. The role of these winds is important in regulating the star formation history of the corresponding central galaxies by determining the temporary removal of material reheated by supernovae explosions and its re-incorporation onto the hot gas of the halo.

In the following, we define as “expanding” all winds with a shock front that is travelling with positive velocity ($v_s > 0$). Typically, winds with negative shock velocities collapse after a few time-steps. Fig. 8 shows the fraction of haloes with an expanding wind as a function of halo virial mass, at different redshifts. A large fraction of haloes with $M_{\text{vir}} < 10^{12.5} M_\odot$ hosts an expanding wind, while no wind can successfully blow out of larger haloes. At early times, the fraction of haloes with an expanding wind is more skewed towards less massive haloes. This is the result of two different

Figure 8. The fraction of haloes that are blowing a wind that is currently expanding, as a function of halo virial mass. A wind is defined as “expanding” when its shock front is travelling with a positive velocity $v_s > 0$. Results are shown at $z = 0, 1, 2, 3$ and 4.5 .

effects: at higher redshifts, smaller haloes become progressively more common and galaxies reside in haloes with lower circular velocities, resulting in more efficient ejection of their gas and metals.

Fig. 9 shows the cumulative distribution of the total amount of metals in winds (upper panel) and of that in expanding winds (lower panel) as a function of halo virial mass. The total amount of metal mass in winds represents all the metals that have been ejected by galaxies and are currently being processed by winds. This quantity does not include the metals that have been deposited into the IGM. Fig. 9 shows that galaxies in all haloes contribute to the recycling of metals in feedback processes. On the other hand, virtually all metals in expanding winds have been ejected by galaxies in haloes with $M_{\text{vir}} < 10^{12.5} M_\odot$, consistently with the result shown in Fig. 8. The thin yellow solid line in the upper panel, defined as DLB07, shows the cumulative distribution of the ejected metal mass in the model of DLB07 at $z = 0$. This closely follows the distribution of the metals in expanding winds at $z = 0$, but not the distribution of the total ejected metals in our model.

Fig. 10 shows the average fraction of the total amount of metals in winds (upper panel) and of the metal mass in expanding winds (lower panel), as a function of halo virial mass. Results are presented at $z = 0, 1, 2, 3$ and 4.5 . The total metal mass M_{Zgas} includes the metals in all the gaseous phases, that is the metals in the hot and cold gas, the metals in winds and those deposited into the IGM, but not the metals locked in stars and black holes. Fig. 10 shows that metals ejection is most efficient in haloes with $10^{11} M_\odot < M_{\text{vir}} < 10^{13}$. Winds that blow out of these haloes are the most efficient to keep a large amount of metals out of galaxies for a long time and can contain up to 80 per cent of all the metals formed in the halo. Galaxies in haloes with $M_{\text{vir}} > 10^{12.5} M_\odot$ can transfer up to 30% of their metals

Figure 9. Cumulative distribution of the total amount of metal mass in winds (upper panel) and of the metal mass in expanding winds (lower panel) as a function of halo virial mass. Results are shown at $z = 0, 1, 2, 3$ and 4.5 .

into a wind, before these are incorporated into the hot gas. The results shown in Fig. 10 are only mildly dependent on redshift.

The thin yellow solid line in the upper panel, defined as DLB07, shows the average ejected metal mass in DLB07 at $z = 0$. This roughly traces the distribution of the total amount of metals in winds at $z = 0$ for haloes with $M_{\text{vir}} < 10^{12.5} M_{\odot}$ in our model, but not the average fraction of the total amount of metals in winds. Together with the result of Fig. 9, this demonstrates to what extent our feedback scheme is different from that of DLB07. In our model supernova feedback in haloes with $M_{\text{vir}} > 10^{12.5} M_{\odot}$ determines the rate at which metals are deposited into the hot cluster gas, via a “wind” phase. The model of DLB07 treats this transfer in a different way, that does not require the temporary deposition of gas and metals in a “wind”

Figure 10. Average fraction of the total amount of metals in winds (upper panel) and of the metal mass in expanding winds (lower panel) as a function of virial halo mass. Results are shown at $z = 0, 1, 2, 3$ and 4.5 .

(see Croton et al. 2006 for details). In DLB07, the hot halo gas can be ejected only if the energy transferred to the hot gas by supernova explosions is larger than the increase of the thermal energy of the halo due to the deposition of the reheated mass. Since this does not happen in haloes with $M_{\text{vir}} \gtrsim 10^{12.5} M_{\odot}$, the hot gas can never be removed from the halo. Hence the difference in the amount of gas being recycled in these haloes in the two models (Fig. 9, upper panel). The different treatment of feedback in haloes with $M_{\text{vir}} > 10^{12.5} M_{\odot}$ also explains why the model of DLB07 produces only red galaxies at the highest stellar masses, while our model still predicts a few blue, late type galaxies, as shown in Fig. 4. The recycling of gas in groups with $M_{\text{vir}} < 10^{13} - 10^{15} M_{\odot}$, and in particular the variations in the mass of hot gas due to the removal and addition of gas by winds, favours the cooling of gas onto the central galax-

Figure 11. The fraction of haloes that have permanently lost their metals as a function of halo virial mass. Results are shown at $z = 0, 1, 2, 3$ and 4.5 .

ies, which may accrete a sufficient amount of gas to form a disk.

5.2 Consequences for the metal enrichment history of the IGM

In this Subsection we focus on the metals in winds that have escaped the gravitational potential of haloes and have reached the Hubble flow. We recall that in our treatment, this material is permanently lost from the halo and therefore does not participate anymore to the evolution of the corresponding central galaxy. When winds reach the Hubble flow, the density field in which they expand cannot be estimated analytically, unless the real 3-dimensional distribution of matter in the simulation is taken into account. We are therefore not able to trace the spatial distribution of these metals. In addition, our model clearly neglects the possibility that metals mixed with the intergalactic gas can be incorporated at later epochs by nearby haloes or by the same parent halo accreting mass from a larger infall region.

Fig. 11 shows the fraction of haloes that have permanently lost metals as a function of halo virial mass, at different redshifts. We find that the higher the redshift, the smaller the total fraction of haloes that have permanently lost their metals. Less than 60 per cent of haloes with $M_{\text{vir}} < 10^{12} M_{\odot}$ have lost metals to the IGM at $z = 0$, and an even smaller fraction at higher redshifts. All the largest haloes have deposited a fraction of their metals into the IGM. This indicates that galaxies forming in the largest haloes have had a sufficiently intense star formation activity to power a wind that ultimately escaped their gravitational potentials and deposited metals into the IGM at least once, while not all galaxies in smaller haloes may experience the same conditions. This result is only weakly affected by changes in the model parameters.

Fig. 12 shows the cumulative distribution of metals permanently deposited into the IGM as a function of halo virial

Figure 12. Cumulative distribution of metal mass permanently lost into the IGM as a function of halo virial mass. Results are shown at $z = 0, 1, 2, 3$, and 4.5 .

Figure 13. Average fraction of metals lost into the IGM as a function of the halo virial mass. Results are shown at $z = 0, 1, 2, 3$ and 4.5 .

mass. Results are shown at $z = 0, 1, 2, 3$, and 4.5 . The behaviour of the distribution at different redshifts gives an idea of the ejection history of these metals. The comparison with Fig. 11 demonstrates that most of the metals lost have been ejected before the source haloes accreted most of their mass. At $z = 4.5$ about 80 per cent of the metals have been ejected by haloes with $M_{\text{vir}} \lesssim 10^{10.5} M_{\odot}$, therefore by haloes with virial masses considerably smaller than those predicted at $z = 0$.

Fig. 13 shows the average fraction of metals lost into the IGM as a function of halo virial mass at different redshifts. Here the average is calculated only over those galaxies that

have lost metals to the IGM. At $z = 0$ galaxies in haloes with $10^{10.5} M_{\odot} < M_{\text{vir}} < 10^{11.5} M_{\odot}$ have deposited on average 40 per cent of their metal mass into the IGM, while groups and clusters have ejected at most a few percent of their metal mass, in agreement with the widely used assumption that the chemical evolution of clusters can be described at first order by a closed-box model. At $z = 4.5$ the galaxies in haloes with $M_{\text{vir}} < 10^{11} M_{\odot}$ are the most efficient to deposit metals into the IGM, while at intermediate redshifts, the peak of the most efficient galaxies moves towards higher virial masses. These results also prove that galaxies in small haloes are the main sources of the metal enrichment of the intergalactic medium and that the haloes that ejected metals into the IGM at early times are the progenitors of groups and clusters at the present time.

To verify that these findings are genuine and do not critically depend on the specific values of the model parameters, we modify the power law index α_w in eq. (7) and (8) and we consider models with $\alpha_w = 1$ and $\alpha_w = 1.5$ (for consistency, the value of the wind initial velocity V_w is also decreased). The smaller the value of α_w , the less mass is lost by smaller galaxies and the larger the mass injected in winds by larger galaxies. However, we find that no matter the value of α_w , haloes with $M_{\text{vir}} < 10^{12.5} M_{\odot}$ are always the most efficient to deposit metals into the IGM, while larger haloes do not lose more than a few percent of their metals. This confirms that the dynamical feedback scheme we present here correctly describes the physical mechanisms that power galactic winds and their effects on galaxies, independently of the actual values of the model parameters.

6 CONCLUSIONS

In this work, we have presented a new feedback scheme which is based on a dynamical treatment of the evolution of galactic winds in a cosmological context. The scheme has been incorporated in the Munich semi-analytic model for galaxy formation described in De Lucia & Blaizot (2007) (see also Croton et al. 2006) and replaces previous implementations of supernova feedback, but does not alter the AGN feedback model. In our scheme, the ejection and recycling of gas and metals is treated self-consistently and is governed by the dynamical evolution of winds, rather than by empirical prescriptions.

Our results demonstrate that such a scheme is a good alternative to empirical recipes for feedback and in particular it is able to reproduce the observed properties of dwarf galaxies with higher accuracy than previous models. Our main results can be summarized as follows:

- (i) The predictions for the the K-band and b_J -band luminosity functions and for the stellar mass function are in good agreement with observations. In particular, the number density of dwarfs reproduced with greater accuracy than in the model presented in DLB07.
- (ii) The stellar mass–stellar metallicity and the luminosity–gas metallicity relationships are in excellent agreement with observations and significantly improve previous results. Again, the improvement is significant for dwarf galaxies.

These results demonstrate that the treatment of feed-

back in dwarf galaxies in our model is significantly improved with respect to previous implementations. We argue that the main reason for this improvement is the possibility of estimating the amount of mass and metals that a halo can permanently lose and deposit into the IGM. This feature determines a stronger quenching of star formation in small haloes and therefore the suppression of the faint end of the stellar mass and luminosity functions of galaxies, and the shape of the mass–stellar metallicity and of the luminosity–gas metallicity relationships.

Our model, however, also exhibits some weaknesses. Firstly, there is a tendency to overestimate the number of bright galaxies in the LFs, because of the continuous recycling of gas when winds recollapse in massive haloes. A possible solution could be an increase in the efficiency of AGN feedback (about 20–30 per cent more intense than suggested by Croton et al. 2006), but this would negatively affect the abundance of galaxies at the knee of the LFs. Our model does not solve the problem of the abundance of M^* galaxies at $z = 0$, which continues to be underestimated (see also Bower et al. 2006). Finally, perhaps the most severe shortcoming of the model is that it does not correctly reproduce the colour distribution of galaxies. In particular, our model results do not exhibit the sharp colour bimodality observed for galaxies in the local Universe. This feature does not depend on the specific values of the model parameters and it can be only slightly alleviated by assuming very inefficient feedback. However, models with inefficient feedback do not correctly reproduce the abundance of dwarf galaxies.

In the second part of our paper, we have investigated the efficiency of the mass and metal injection in winds and into the IGM. We have shown that in our model, galaxies in haloes with $M_{\text{vir}} \lesssim 10^{12.5} M_{\odot}$ lose most of the metals injected into winds into the IGM, being the only objects that can blow winds out of their gravitational potentials. Larger haloes like groups and clusters lose only a small fraction of their mass and metals, and this occurs before most of the halo mass is accreted.

Our feedback model contains the same number of free parameters (i.e. 3) as the feedback model of Croton et al. (2006), once the dependence of the ejected mass on the halo virial velocity in Croton et al. (2006) (this corresponds to our parameter α_w) is taken into account. The numerical calculation of the evolution of winds is only slightly more time-consuming than previous feedback schemes. However, it does require about 10–15 per cent additional memory to handle the wind variables and to store them on disk, if desired.

ACKNOWLEDGMENTS

We would like to thank Jon Loveday and Bernard Pagel for useful discussions and Simon White for reading the manuscript. SB is supported by PPARC. The Millennium simulation was carried out by the Virgo Consortium at the Max Planck Society in Garching. Data on the galaxy population produced by this model, as well as on the parent halo population, will be publicly available at <http://www.mpa-garching.mpg.de/millennium/>.
